Abstract

This document is a programmer's guide for modifying and extending the Access Grid software environment.

1 Introduction

2 Package breakdown

The VV software is broken into a number of different Python packages. These packages are rooted in a hierarchy based at package AG.

Module name	Purpose
AG.services.xmlrpc	XMLRPC-based web services library
AG.services.venue	The AG Venues service implementation
AG.apps.venue	The AG Venues client
AG.apps.shared_web	AG shared web browser
AG.apps.docking_tools	Standard collection of workspace docking tools
AG.tools.agsd	AG service description processing tool

3 Venue description language

In a number of locations in the virtual venues system it is useful to provide the user with a free-form abstract mechanism for describing objects (users, venues, services, etc). We define a description model which allows ample expressiveness in the representation of description data while using simple data structures. We desire the use of simple data structures to enable the use of high-level scripting languages. It also allows us to effectively leverage the use of the XMLRPC protocol for remote procedure invocation. XMLRPC supports the following data types (from [XML-RPC HOWTO](#)):

Data type	Description
<i>int</i>	A signed, 32-bit integer.
<i>string</i>	An ASCII string, which may contain NULL bytes.
<i>boolean</i>	Either true or false.
<i>double</i>	A double-precision floating point number. (Accuracy may be limited in some implementations.)
<i>dateTime.iso8601</i>	A date and time.
<i>base64</i>	Raw binary data of any length; encoded using Base64 on the wire.
<i>array</i>	An one-dimensional array of values. Individual values may be of any type.
<i>struct</i>	A collection of key-value pairs. The keys are strings; the values may be of any type.

Given this background, we can now define a description. It is simply an unordered set of tag/value pairs, where the tags are strings and the values are any of the basic types enumerated above. This maps naturally to the XMLRPC struct data type. In Python, a description maps to a dictionary.

Given this background, the real meaning and utility of a description lies in a common definition of tag names and their meaning. The virtual venues software uses the following standard descriptions.

3.1 User

A user description provides the information about a logged-in user. This description is present in the venue when the user is present. The following information is provided by the venue itself.

Tag name	Definition
<i>secure_flag</i>	True (1) if user has connected using an authenticated channel.
<i>identity</i>	User's authenticated identity.
<i>entry_id</i>	The unique identifier of this user's connection to the venue.
<i>preferences</i>	User's client preferences, as advertised by the user's client.
<i>description</i>	User's description, as advertised by the user's client.

The *description* contains the following information, as provided by the reference implementation of the venues client:

Tag name	Definition
<i>name</i>	User's name
<i>email_address</i>	User's email address
<i>phone_number</i>	User's phone number
<i>institution</i>	User's institution
<i>url</i>	User's personal url
<i>toolbar_handle</i>	Service handle for the client's toolbar service

3.2 Venue

A venue description is generated by the venue service and returned to its clients upon execution of the `enter` or `refresh_state` operations.

Tag name	Definition
<i>user_list</i>	Array of user descriptions, one for each logged-in user
<i>media</i>	Array of media descriptions
<i>connections</i>	Array of connection descriptions
<i>service_registry</i>	Handle of the service registry for this venue.
<i>description</i>	Description defining the persistent attributes of this venue

The persistent description mentioned above contains the following tags.

Tag name	Definition
<i>name</i>	Venue name.
<i>description</i>	Textual description of the venue.

4 `AG.services.venue` — Access Grid Venue Server

This package contains the reference implementation of the Access Grid Virtual Venues server. It is composed of several modules:

`AG.services.venue.client` Tools for venues clients

4.1 `AG.services.venue.VenueService` — The Venue service interface module

4.2 `AG.services.venue.VenueServiceImpl` — Venue service implementation module

4.3 `AG.services.venue.VenueServer` — The Venue server itself.

4.4 `AG.services.venue.VenueUser` — User state for Venues users

4.5 `AG.services.venue.client` — Tools for clients

The `client` module provides a set of classes and methods that abstract away the details of the communication between the venue client and service. Via the mechanisms provided in the `client` module, the application writer can concentrate on the details of the application itself and manipulate the venue data at an appropriately high level.

A Venue provides several types of data to the client. Each of these data types is made available through the `client` interface encapsulated in a Python object. *However, we currently only wrap users in objects.*

class `ClientVenueInterface`()

The `ClientVenueInterface` class is the primary interface the client uses to talk to the venue.

class `User`(*user_desc*, *is_local*)

An instance of the `User` class contains the information maintained by a venue about that user.

`ClientVenueInterface` objects

The `ClientVenueInterface` class provides the following methods.

`get_description`()

Returns the dictionary used to construct the description of this client. See Section 3 for more information on how descriptions are defined.

`get_preferences`()

Returns the dictionary used to construct the preferences for this client. *Preferences are not currently implemented.*

`connect`(*service_handle*)

Connect to the Venue service at handle *service_handle* by invoking the `enter` service operation.

This method messages the venue service with the current description and preferences as configured in the client. If the client is allowed to enter the venue, the venue returns the description of the venue. The `ClientVenueInterface` digests this description and makes the data available to its users via the `get_service_registry`, `get_connections`, `get_user_list`, `get_media_channels`, and `get_venue_description` methods.

`disconnect`()

Disconnect the client from the venue by invoking the `exit` service operation on the venue.

`reconnect`()

If the client is already connected, `disconnect`. Then `connect` to the service previously connected to.

`keepalive`()

Invoke the `keepalive` operation on the venue to keep this client's soft state registration from timing out.

`refresh`()

Invoke the `refresh_state` operation on the venue service to obtain a new description for the venue. Digest the description in the same manner as `enter`.

`get_service_registry`()

Return the service registry handle for the venue, if present.

`get_connections`()

Return the list of connections present in the venue. The connection list is a python list of tuples (`connection_name`, `connection_handle`).

`get_user_list`()

Return the list of users in the venue. Each user is an instance of the `User` class.

get_media_channels()

Return the list of media channels in the venue. Each channel is (currently) a tuple (media, address, port), where media is video for a video channel and udaiio for an audio channel.

get_venue_description()

Returns the full venue description dictionary.

get_my_id()

Returns the unique identifier for this client.

User objects

The User object provides the following methods.

is_local_user()

Returns true if this user object corresponds to the currently-executing application.

get_DN()

If the user authenticated to the venue using a secure connection, return the distinguished name for that authentication. Other, return *None*.

get_id()

Return the user's unique identifier (as assigned by the venue).

get_name()

Return the user's name.

get_attributes()

Return the user description as a Python dictionary.

get_attribute(key)

Look up and return the user description entry for *key*.
